1 Introduction

Enormous datasets are a common case in today's applications. Compressing the datasets is beneficial, because they naturally decrease memory requirements but also are faster when compressed data is read from disk (Zobel and Moffat, 1995).

One of the leading methods of data compression is variable-length coding (Salomon, 2007), where frequent sequences of data are represented with shorter codewords. Because the sequences of data have different lengths when compressed, it is not trivial to determine the exact location of a certain element. If this is required, the usual data compression algorithms are inefficient. Fortunately this is not a requirement compression algorithms usually need to fulfill.

However, random access of compressed data is needed in compressed data structures. In most compression methods, the only way to this is to decompress data from the beginning. An integer compressing method with fast random access is explained later and compared existing state-of-the-art methods.

2 Variable-byte encoding

Variable-byte (VB) encoding (Williams and Zobel, 1999) is a method of compressing integers via omitting leading zero bits. In normal data sets, it loses in compression performance to generic algorithms like Huffman encoding or Lempel-Ziv encoding, but in comparison it's faster to decode (Brisaboa et al., 2009) and sometimes preferred due to its simplicity. allows constant time random access. This is later explained in (TODO: link to later chapter).

A good data set for VB encoding is a list of mostly small numbers with a need to support larger ones. A search engine may use an inverted index of words in documents. For each word, a list of document IDs where the word appears is stored. It may also store locations of the word in document for advanced search purposes. Usually these lists are preprocessed and stored as an inverted index or gaps, storing the difference to previous number instead of the actual number (Manning et al., 2008). Common words have a lot of entries in these lists, but because of gap storing the numbers are small. In contrast, rare words have only a few entries but the numbers stored are larger. These lists are excellent data sets for VB encoding.

VB encoding splits each integer into blocks of b bits and adds a continuation bit to the block to form chunks of length $1 + b$. The extra bit is set to 1 only on the block containing the least significant bits of the integer. This information is used in decoding to signal if next chunk continues the current integer. For example, let's assume $b = 4$ and let $n = 42$ be a 16 bit unsigned integer. The standard 8-bit representation of n is 00000000 00101000. When split to blocks of b bits, it becomes 0000 0000 0010 1000. Empty blocks are omitted and continuation bits are added to the remaining blocks. The result is 00010 11000, which is the compressed data.

```

function VBENCODENUMBER(n)
  bytes  $\leftarrow$  list
  while true do
    bytes.prepend(n mod 128)
    if n < 128 then
      break
    n  $\leftarrow$  n div 128
  bytes.last() += 128
  return bytes

function VBENCODE(numbers)
  bytestream  $\leftarrow$  list
  for each n  $\in$  numbers do
    bytes  $\leftarrow$  VBEncodeNumber(n)
    bytestream.extend(bytes)
  return bytestream

```

Figure 2.1: VByte encoding

Decoding is essentially just reversing the encoding steps: chunks are read until a chunk with 1 as continuation bit is found. Continuation bits are removed from all the chunks and the blocks are concatenated to form the original number. As in the previous example, $b = 4$, encoded message is 00010 11000 and $n = 0$. Block from the first chunk is extracted and added to n , making $n = 10$. A bitwise shift to left equal to b is applied to n , changing $n = 100000$. Then the block is extracted from the next chunk. This block is added n , making $n = 42$. Because the previous continuous bit was 1, decoding this number has finished. An example implementation of encode and decode with block length of 7 is shown in Figure 2.1 and Figure 2.2.

```

function VBDECODE(bytestream)
  numbers  $\leftarrow$  list
  n  $\leftarrow$  0
  for each b  $\in$  bytestream do
    if b < 128 then
      n  $\leftarrow$   $128 \times n + b$ 
    else
      n  $\leftarrow$   $128 \times n + b - 128$ 
      numbers.append(n)
      n  $\leftarrow$  0
  return numbers

```

Figure 2.2: VByte decoding

Small lengths of c can yield better compression rate at the cost of more bit manipulation, while longer chunks need less bit manipulation and offer less effective compression. Gen-

erally block length of 7 has been used because it gives a good average and handling chunks as bytes is convenient (Manning et al., 2008).

VB encoding is a well known compression algorithm. It's origins date back to 1980's and the famous MIDI music file format. It stored some of the numbers in a "variable-length quantity" form, which was a 7-bit block VB structure (Association, 1996). Similar data types have existed for example in Apache Lucene (as vInt) and IBM DB2 database (as Variable Byte). Later, VB encoding was found efficient in compressing integer lists. It was first experimented in compressing inverted index lists of word locations in documents (Scholer et al., 2002). That yielded excellent records, and since then many different approaches have been introduced.

Modern studies have looked into machine code for VB and applied SIMD (Single instruction, multiple data) architecture to VB (Lemire et al., 2018; Plaisance et al., 2015). The bit operations in VB are simple and therefore modifying the code to use SIMD instructions is straightforward and the speed improvements are significant.

TODO: might need 1-2 more chapters

3 Directly addressable codes?

Ability to handle large amounts of data fast is one of the key challenges in the field of search engines. Compressed data structures are applied to fit the data into cache, memory or even hard drive. Direct access to any element is one of the usual requirements in compressed data structures. It is not natively possible to decode the i -th element in variable-byte compression algorithms, because the position of the element depends on the length of the preceding compressed data.

Direct access is achievable with supporting data structures. An obvious solution is to store the location of each element, but it adds a very large overhead which removes the benefit of compression.

3.1 Rank and Select

Rank and select are two succinct data structure operations which operate on a bit array B . $Rank_1(B, i)$ gives the sum of 1 bits between $B[0]$ and $B[i]$ and $select_1(b, i)$ gives the index of i -th 1 bit in B . Both operations work in constant time (citation?). Locations of 1 bits in B should represent locations of the items in the encoded data. For most compression algorithms, this requires B to be created in addition to the existing data and the length of B usually has to be close to the length of the data. VB encoding has several advantages with search and rank: its data is compressed in blocks of equal length which significantly shrinks the length of B . Also the bit array C formed from the continuation bits already stores the locations of items. In this case, $rank_1(C, i)$ would give the sum of end bytes up to i -th index and $select_1(C, i)$ would give the location of the ending byte of i -th compressed element.

3.2 Rank and Select implementation

The rank and select implementations used in this article are C++ libraries from (Gog et al., 2014). The library has several implementations of both rank and select as well as an implementation of a bit array. Table 3.1 has *rank* and *select* size requirements of

Table 3.1: Memory requirements of SDSL rank and select data structures

| Structure | Extra size taken |
|-----------|--------------------------------|
| Rank | 25% of bit array |
| Rankv5 | 6.25% of bit array |
| Select | 8.3% of bit array (on average) |

implementations used in this experiment. Both rank implementations have a constant space requirement, while select’s needed size depends on the number of 1’s in the data.

For every 512th bit in the array, rank stores the absolute value of 1’s preceding that bit in a superblock. For every 64th bit in a superblock, a relative count is stored. With this setup, an rank can be instantly calculated for every 64th bit. To get $\text{rank}(i)$, $\text{superblock}[i/512]$ and it’s relative value $(i\%512)/64$ are fetched. Then 1 bits from $(i-i\%64)$ to i are counted and added to get the correct sum. For Rankv5, superblock size is 2048 and relative count is stored every 384th bit, which offers a tradeoff between performance and memory usage.

Select data structure works similarly to rank. Index location of every 4096th set bit is stored in the superblock and location of every 64th set bit is stored relative to the superblock.

3.3 DAC via rank

Directly addressable codes in VB was first introduced by (Brisaboa et al., 2009) in 2009. Their solution was to divide chunks in encoded bytes to separate arrays A_1 to A_n and then use rank_0 to get direct access. If i is the requested index, then $\text{rank}_0(A_k, i)$ returns the number of elements preceding i that have continuation bit set at 0. In other words, the number of elements that continue to A_{k+1} .

For example, if an element needed 3 chunks when encoded, the least significant bits would go to A_1 , second least significant bits to A_2 and the most significant bits would go to A_3 . When fetching i -th element, getting the first chunk is just fetching $A_1[i]$. If the continuation bit is set at 0 (meaning there are more chunks to this element), getting the correct index for A_2 is calculated with $\text{rank}_0(A_1, i)$. A pseudo code example of DAC with rank is shown in Figure 3.1 with block length of 8. (TODO: example needed?)

```

i ← wanted index
A ← block arrays
B ← continuation bit arrays
level ← 0
number ← 0
while B[level][index] = 0 do
    block ← A[level][index]
    number ← number ≪ 8
    number ← number | block
    index ← RANK(B[level], index)
    level ← level + 1
block ← A[level][index]
number ← number ≪ 8
number ← number | block

```

Figure 3.1: Example pseudo code of DAC with rank by Brisaboa et al.

4 DAC with select query

Using $select_1$ on the continuation bit array to achieve direct access is more intuitive than using $rank_1$. The element locations are already marked with 1's in B and a single $select_1$ query gets the desired starting point, while the forementioned version (Brisaboa et al., 2009) used one $rank$ query for each chunk beyond the first. Minimizing the amount of $select$ and $rank$ queries is important. They run in constant time but their impact is huge, because rest of the VB decoding consists of a few bit operations.

To use $select_1$ with VB, continuation bits need to be separated from chunks to their own bit array and a $select_1$ structure built over it. $Select(i)$ returns the location of the end byte of i -th element. Therefore the start of j -th element in the block array is at block $b_s = select_1(j-1) + 1$. To simplify calculations even further, block sizes of 4 and 8 were used to avoid splitting of blocks between bytes.

Unlike the standard VB encoding, the continuation bits are not in the middle of the data blocks. The compressed number can be read from the memory block and concatenation of blocks is not needed. The data in blocks is be written into memory as it is, so that when reading a large unsigned integer from the block byte array, the bits are already in correct order.

If the original element size is 32 bits and the data was compressed to k blocks of length b . The starting byte s of the element is $select(i) * b \text{ div } 8$ where div is the integer division. Offset o is the remainder of previous division, $o = x*b \text{ mod } 8$. The 32-bit value is read from memory from byte location s . Then bit shift left for $32-b*k-o$ is applied to remove trailing bits and bit shift right $32-b*k$ to re-align bits. If block size is one byte, offset calculation is not needed and thus the process is slightly faster.

The intuitive way to calculate block length k of i -th element is from $select_1(i+1)$ and subtract previously calculated start block index from it. This however causes a second $select_1$ query, which is costly. A much faster option is to iterate forward in bit array until the next 1. Alternatively, the block length can be calculated by reading an integer from the bit array, aligning it's offset and counting the trailing zeros. Figure 4.1 contains an example of VB encoding with DAC with $select$ and block size 8. Different block sizes need extra calculation to get the block location from the byte array. In the example, *CalculateLength* returns the length of the number in blocks and *ByteMask(k)* returns a

bit mask for k bytes.

(maybe to future work) Storing bytes in this fashion may have benefits when reading subsequent (fast next() and previous()?) elements. With some modifications, SIMD instructions can possibly be applied.

```

i ← wanted index
A ← block byte array
B ← continuation bit array
begin ← SELECT(index)
len ← CALCULATELENGTH(begin)
mask ← BYTEMASK(len)
number ← A[begin]                                ▷ read a larger number from the byte array
number ← number & mask

```

Figure 4.1: Pseudo code of DAC with select with block length 8

TODO: try bitvector SD performance + size (select)

TODO: look into select implementation, may need optimizing

5 Experimental results

The following experiments are run on ~~at the moment my work~~ Lenovo Thinkpad T480s, ~~TODO run on a server and write specs here~~. The algorithms were implemented with C++ (~~TODO: list compile tags and whatnot here~~) using data structures and functions from (Gog et al., 2014).

Five different kinds of VB decoding algorithms were used. Bris-implementations are from (Brisaboa et al., 2009).

- Bris4v5 - Bris implementation with block size 4, using rank support v5
- Bris8 - Bris implementation with block size 8, using rank support v
- Bris8v5 - Bris implementation with block size 8, using rank support v5
- Our4 - Our implementation with block size 4, using select support mcl
- Our8 - Our implementation with block size 8, using select support mcl

Eight kinds of datasets were used. For each number in the dataset, p was randomly selected from P and then number was randomly selected from range $[0, 2^p]$.

- all5M - 5 million numbers, $P = 7, 8, 15, 16, 23, 24, 30, 31$
- all50M - 50 million numbers, $P = 7, 8, 15, 16, 23, 24, 30, 31$
- byte5M - 5 million numbers, $P = 7, 7, 7, 8, 8, 8, 16, 31$
- byte50M - 50 million numbers, $P = 7, 7, 7, 8, 8, 8, 16, 31$
- small5M - 5 million numbers, $P = 3, 4, 5, 6, 7, 8, 16, 31$
- small50M - 50 million numbers, $P = 3, 4, 5, 6, 7, 8, 16, 31$
- vsmall5M - 5 million numbers, $P = 2, 2, 3, 3, 3, 4, 4, 15$
- vsmall50M - 50 million numbers, $P = 2, 2, 3, 3, 3, 4, 4, 15$

Table 5.1: Results in milliseconds, smaller is better.

| Experiment | all5M | all50M | byte5M | byte50M | small5M | small50M | vsmall5M | vsmall50M |
|------------|--------------|---------------|--------------|---------------|--------------|---------------|--------------|--------------|
| Bris4v5 | 348.41 | 768.83 | 345.16 | 772.84 | 344.54 | 768.45 | 346.86 | 771.61 |
| Our4 | 127.92 | 263.22 | 127.44 | 263.5 | 127.9 | 262.67 | 127.88 | 262.58 |
| Bris8 | 97.75 | 308.17 | 98.47 | 309.6 | 98.14 | 307.81 | 97.99 | 308.09 |
| Bris8v5 | 127.83 | 287.46 | 127.7 | 288.63 | 128.14 | 291.32 | 127.99 | 287.84 |
| Our8 | 103.85 | 230.16 | 103.92 | 230.14 | 103.86 | 230.02 | 103.95 | 230.6 |

All algorithms save the data to memory and randomize one million index numbers to an array. The time taken is calculated from looping through the index array and VB decoding the number in the index. The times shown in Table 5.1 are an average of 100 such runs.

- do cache grind - - use array instead of vector/joint8 t_j for bris? - comparison to basic implementation + Bri09 - compare with b=2,4,8
- do we need to support search()? - SIMD?

6 Future work

- something to improve / research?

7 Conclusions

It is good to conclude with a summary of findings. You can also use separate chapter for discussion and future work. These details you can negotiate with your supervisor.
